Abstract
The work aims to study the properties of the methane-olefin mixture for application in well control context. Tests were carried out using a PVT cell and different molar fractions of methane, pressures and temperatures.

Key words:
Drilling fluids, Methane, Olefin.

Introduction
The study of the properties of drilling fluids is fundamental for the control of wells during drilling, in order to avoid the occurrence of kicks or even blowouts. Drilling fluids have the role of ensuring the safety of drilling and one of its main functions is to maintain a hydrostatic pressure in the reservoir to ensure that the formation gases do not invade the well2–3. The present work provides studies of the properties of the methane-olefin mixtures for different gas molar fractions performed in a PVT cell under high pressure and high temperature.

Results and Discussion
The tests were conducted in a PVT cell by the Constant Composition Expansion (CCE) procedure, that consists of the expansion of fluid under constant temperature, through the application of constant pressure gradients. During the test, the pressure, volume, and temperature are recorded2–3. The tests were performed with different molar fractions (y) of methane in the mixture (10, 20, 30, and 40%), in the temperatures (T) of 20, 25, 40, 60, and 80°C, and pressures (P) up to 8000 psi. The tests were run in duplicate and the PVT results recorded were applied in mathematical equations to obtain the mixture properties such as bubble point (P_bubble), specific mass (ρ), solubility (R_s), and oil formation volume factor (B_o). The results can be found in Chart 1 and Image 1.

The specific mass of the mixture decreases as the temperature and pressure increase at saturation condition. The oil formation volume factor presents the opposite behavior, increases as the temperature and pressure increase. As expected, the saturation pressure rises with temperature and solubility as well. Comparing the results obtained in the present work with previous ones carried out in the laboratory using another type of olefin and n-paraffin2–3 drilling base fluids (Chart 2), it may first be noted that the solubility of methane is lower in the present olefin, which shows good potential in the control of kicks.

Conclusions
It can be concluded that the olefin has an optimal application in the well control, and its performance testifies the usage as a base of drilling fluids.
